# Chapter 1

## Introduction

### 1.1 Problem statement and societal relevance

The current trend in machine learning is moving towards increasingly large models and datasets [1]. Although deep learning approaches often achieve the highest predictive accuracy, their energy demand and associated  $CO_2$  emissions increase disproportionately [2, 3]. In an era marked by strict sustainability guidelines and rising energy costs, a critical question arises: At what point is a computationally "simple" model ecologically more viable than a highly complex one?

The primary objective of this thesis is to determine whether and when it is worthwhile to deploy more complex models, considering not only their predictive accuracy but also their associated energy consumption. To achieve this, a Logistic Regression, a Random Forest, an XGBoost model and a Multilayer Perceptron are compared under equal conditions across three datasets of varying sizes. This comparative analysis aims to provide a clearer understanding of the thresholds at which simpler models represent the better choice. Additionally, the study investigates how modifying a Multilayer Perceptron architecture, specifically varying the number of neurons and hidden layers, directly impacts energy consumption and  $CO_2$  emissions.

To address the problem statement and achieve the outlined objectives, this thesis investigates the overarching question: *How does the relationship between energy consumption and predictive accuracy change for Logistic Regression, Random Forest, XGBoost, and Multilayer Perceptron when model complexity and dataset size are systematically varied?*

Specifically, the following sub-questions are examined:

- How do energy consumption (in kWh) and  $CO_2$  emissions change when scaling a deep learning architecture (variation of neuron count)?
- Under which conditions (dataset size, model complexity) does the resource consumption of complex models exceed the achievable accuracy gain compared to simpler algorithms?

- How does the energy consumption differ between CPU-based training (Random Forest) and GPU-accelerated training (XGBoost, MLP) for the same classification task?

## 1.2 Motivation: When does a simpler model pay off?

## 1.3 Research questions and objectives

## 1.4 Structure of the Thesis

The remainder of this thesis is structured as follows: Chapter 2 provides the theoretical background, distinguishing between Green AI and Red AI, and introducing the relevant sustainability and classification metrics. Chapter 3 details the methodology, including dataset selection and the experimental hardware setup. Chapter 4 outlines the implementation process, focusing on data preprocessing, model training, and the logging of resource consumption. The empirical results are analyzed in Chapter 5, evaluating both performance and resource utilization across scaling dataset sizes. Chapter 6 discusses the findings, highlighting the economic and environmental implications. Finally, Chapter 7 concludes the thesis and provides actionable recommendations for sustainable machine learning practices.

$$S = \frac{F_1}{1 + \lambda_1 \cdot t_{\text{scaled}} + \lambda_2 \cdot c_{\text{scaled}}}$$

# Chapter 2

## Theoretical Background

### 2.1 Metrics

### 2.2 CodeCarbon

*CodeCarbon* is an open-source Python library for measuring the carbon footprint of code running on local hardware. Emissions are calculated as the product of two factors: the energy consumed by the hardware in kWh, and the carbon intensity of the local electricity grid in gCO<sub>2</sub>eq/kWh. Carbon intensity is determined based on the country in which the experiment is run, using data from Our World in Data. The resulting emissions are expressed in kilograms of CO<sub>2</sub>-equivalents (kgCO<sub>2</sub>eq), a standardized measure that accounts for the global warming potential of different greenhouse gases [3].

Power consumption is sampled at 15-second intervals. Rather than relying on instantaneous power readings, *CodeCarbon* derives average power from accumulated hardware energy counters. Instead, it computes the energy delta between two consecutive measurements and divides by the elapsed time to derive average power. This approach is more robust against short-term fluctuations and provides a stable average over each measurement interval [4]. For NVIDIA GPUs, energy is read directly from hardware counters via the `nvidia-ml-py` library, providing accurate device-level measurements. RAM is estimated by *CodeCarbon*, specifically using a flat value of 5 watts per DIMM slot.

CPU measurement depends on the operating system and processor. On Linux, *CodeCarbon* reads energy directly from *RAPL* (Running Average Power Limit) hardware counters, which support both Intel and AMD processors [5]. On Windows, however, *RAPL* is not accessible. *CodeCarbon* therefore falls back to a TDP-based estimation: it identifies the CPU model from a database of over 2000 processors and assumes an average consumption of 50% of TDP. On systems where direct CPU energy measurement is unavailable, this TDP-based fallback may introduce inaccuracies, as TDP represents peak power rather than typical operating consumption.

## Experimental Design

This chapter outlines the experimental design used to evaluate the ecological efficiency of different machine learning classification algorithms. It describes the datasets, models, evaluation metrics, hyperparameter tuning and measurement setup that form the basis of this empirical analysis.

### 4.1 Research Questions

The main research question that this study aims to answer is: *How does the trade-off between energy consumption and predictive performance vary across Random Forest, XGBoost and MLP models when the complexity of the models and the size of the dataset are systematically varied?* The following sub-questions will also be addressed in the course of this thesis:

- Under what conditions do the resource consumption of more complex models exceed the achievable accuracy gain over simpler baselines?
- How does energy consumption and CO2 output scale with increasing neural network complexity (number of layers and neurons)?
- How does energy consumption differ between CPU-based and GPU-based training for equivalent tasks?
- How does reducing the number of training instances on large datasets affect model accuracy and energy consumption across different algorithms?

To answer these questions multiple classification algorithms and datasets were used in the experimental phase of this empirical analysis.

### 4.2 Datasets

Dataset size is a primary driver of both computational demand and energy consumption during model training [6]. To evaluate how this relationship varies across different scales,

three classification datasets were selected that span several orders of magnitude in size. Classification was chosen as the task type since it is well-established across all selected models and allows for direct comparison of predictive performance via standardized metrics such as accuracy and F1-score. The datasets are summarized in Table 4.1.

Table 4.1: Overview of datasets used in this analysis

| Dataset                            | Instances  | Features | Classes | Scale  |
|------------------------------------|------------|----------|---------|--------|
| Wine [7]                           | 178        | 13       | 3       | Small  |
| Default of Credit Card Clients [8] | 30,000     | 23       | 2       | Medium |
| HIGGS [9]                          | 11,000,000 | 28       | 2       | Large  |

The *Wine* dataset contains 178 instances across 13 features, where each feature describes a chemical property of wines from the same region in Italy, derived from three different cultivars.

The *Default of Credit Card Clients* (hereafter: *Credit*) dataset contains 30,000 instances across 23 features and focuses on predicting payment default among credit card clients in Taiwan.

The *HIGGS* dataset is the largest dataset used in this study, comprising 11,000,000 instances across 28 features, seven of which are high-level features derived by physicists to help discriminate between the two classes [10]. The classification goal is to distinguish between signal events produced by Higgs bosons and background noise processes.

These three datasets vary significantly in size, enabling a systematic evaluation of how model performance and energy consumption scale across different levels of data complexity.

## 4.3 Models

Selecting models of varying complexity is central to answering the research questions of this study. A model that achieves competitive accuracy with significantly lower energy consumption represents a more ecologically efficient choice, but this trade-off can only be quantified if the comparison spans a meaningful range of complexity. For this reason, five classification models were selected, ranging from a linear baseline to tree-based ensemble methods and a neural network, covering low, medium, and high computational demand respectively.

Table 4.2: Overview of classification models used in this study

| Model                    | Type              | Device    | Role            |
|--------------------------|-------------------|-----------|-----------------|
| Logistic Regression [11] | Linear            | CPU       | Baseline        |
| Random Forest [12]       | Ensemble          | CPU       | Mid-complexity  |
| XGBoost [13]             | Gradient Boosting | CPU & GPU | Mid-complexity  |
| Multilayer Perceptron    | Neural Network    | GPU       | High-complexity |

Logistic Regression serves as the lightweight baseline in this study. Despite its simplicity as a linear classifier, it often achieves competitive accuracy, making it well suited to quantifying whether the additional resource consumption of more complex models yields a meaningful gain in predictive performance.

Random Forest was selected as a mid-complexity representative of tree-based ensemble methods, as extensively described in Section 2.x . Relevant to this study, Random Forest does not support GPU-accelerated training and is therefore run exclusively on the CPU.

Building on the tree-based approach, XGBoost was chosen as a second mid-complexity model, with the key distinction that it also supports GPU-accelerated training. This makes it possible to directly compare the energy consumption and training time of CPU- and GPU-based tree ensemble methods under identical conditions, which is central to one of the research questions of this study.

The MLP was selected as the most complex model, representing the deep learning category. Its highly configurable architecture, particularly the number of hidden layers and neurons per layer, makes it well suited for the architectural complexity experiments conducted in this study, where these parameters are systematically varied to assess their impact on predictive performance and energy consumption. A more detailed description of the MLP architecture is provided in Section 2.x.

Together, the selected models cover a broad spectrum of algorithmic complexity, from a linear baseline to gradient boosting and deep learning, enabling a meaningful comparison of both predictive performance and energy efficiency across fundamentally different model types. The following section defines the metrics used to evaluate these dimensions.

## 4.4 Evaluation Metrics

To answer the research questions of this study, two categories of metrics were employed: classification performance and resource consumption. Accuracy and weighted F1-Score were selected to measure predictive performance, as they provide a standardized basis for comparing models across datasets of varying class distributions, as further described in Section 2.1. Energy consumption in kWh and  $CO_2$  emissions in kg were chosen as the primary resource metrics, directly reflecting the ecological cost of model training. It should be noted that all experiments were conducted on a single hardware setup, which is described in detail in Section 5.1.1.

Training time in seconds was included as a secondary resource metric, as it captures computational demand independently of hardware-specific power draw. Furthermore, inference time was measured across all experimental setups to account for the operational footprint. In large-scale deployment scenarios, the cumulative energy demand of repeated predictions can often rival or even exceed the initial training costs [14]. Together, these metrics enable a direct assessment of whether gains in predictive performance justify the associated increase in resource consumption.

Inspired by the efficiency framing proposed in Schwartz et al., a custom composite metric was developed for this study, named the *Efficiency-Weighted F1* (EWF1), defined as:

$$\text{EWF1} = \frac{F_1}{1 + \lambda_1 \cdot \hat{t} + \lambda_2 \cdot \hat{c}} \quad (4.1)$$

where  $\hat{t}$  and  $\hat{c}$  denote the min-max normalized training time and CO2 emissions per dataset respectively. The weights were set to  $\lambda_1 = 0.5$  and  $\lambda_2 = 1.0$ , assigning greater importance to carbon emissions than training time, reflecting the ecological focus of this study. Higher scores indicate a more favorable trade-off between predictive performance and resource consumption.

It should be noted that both  $\hat{t}$  and  $\hat{c}$  are inherently hardware- and location-dependent, as training time varies with the underlying hardware configuration and CO2 emissions are tied to the carbon intensity of the local electricity grid [1]. Consequently, EWF1 scores reflect the ecological efficiency of the specific experimental setup used in this study and may not generalize directly to other hardware or energy infrastructures.

## 4.5 Validation Strategy

To obtain reliable and generalizable performance estimates, a cross-validation strategy was employed rather than a single train-test split, as described in Section 2.x.

Specifically, K-Fold cross-validation was applied with  $k = 5$  folds, a value widely recommended in the literature as a practical balance between computational cost and estimation stability [15]. Each model is trained and evaluated five times on non-overlapping subsets of the data, and the final performance score is averaged across all folds. This approach is consistent across all models and datasets, ensuring comparability of results.

To ensure reproducibility, a fixed random state was used for all cross-validation splits, model initialization, and data shuffling. The specific value and its technical implementation are described in Section 5.1.2.

## 4.6 Hyperparameter Tuning

To ensure a fair comparison across all models, hyperparameter tuning was applied to each model prior to evaluation. Without tuning, default parameters tend to favor certain model families over others, potentially skewing the comparison in terms of both predictive performance and resource consumption [16].

Hyperparameter optimization was performed using Optuna [17], an optimization framework based on Bayesian search (see Section 2.x).

Hier in 02 die genaue Erklärung

Grid search was considered but deemed infeasible given the scale of experiments: assuming five hyperparameters per model with ten candidate values each, evaluated across

three datasets and four models, a full grid search would require approximately 150,000 evaluations. Optuna was therefore configured to run 50 trials per model per dataset, striking a balance between tuning thoroughness and resource consumption, the latter being a relevant factor given that tuning runs contribute to the overall energy budget of this study, as described in Section 4.4.

Weighted F1-score was used as the optimization objective, as it accounts for class imbalance more robustly than accuracy, providing a more reliable estimate of model quality across datasets with varying class distributions.

Tuning was performed separately for each dataset, as the datasets differ substantially in size, feature space, and class distribution. A globally tuned model would not represent optimal performance on any individual dataset and would therefore introduce bias into the comparison.

# Chapter 5

## Implementation and Measurement

### 5.1 Experimental Setup

#### 5.1.1 Hardware Setup

A critical decision in the experimental design was the selection of the computing platform on which all experiments would be conducted. Two options were considered: the university’s shared computing infrastructure or a local machine. The latter was ultimately chosen, as it provides several key advantages for this study. First, it ensures complete reproducibility, since all experiments are executed on identical hardware configuration, eliminating interfering variables that could arise from shared resource conflicts or system variability. Second, it provides consistent availability and direct control over system configuration, which is particularly important given the extended runtime of the large-scale experiments (particularly on the 11M-instance HIGGS dataset). Third, local execution facilitates fine-grained performance monitoring and measurement of energy consumption, a primary objective of this study.

The hardware platform selected for all experiments is a consumer-grade desktop system with the following specifications: an NVIDIA RTX 4070 graphics processing unit (12 GB GDDR6 memory, 5,888 CUDA cores), an AMD Ryzen 7 5700X processor (8 cores / 16 threads, base clock 3.6 GHz), and 32 GB of DDR4 RAM. The system runs Windows 11 with all code implemented in Python 3.12.0.

Table 5.1: Hardware specification of the experimental system

| Component        | Specification                                          |
|------------------|--------------------------------------------------------|
| CPU              | AMD Ryzen 7 5700X (8 cores / 16 threads, 3.6 GHz base) |
| GPU              | NVIDIA RTX 4070 (12 GB GDDR6, 5,888 CUDA cores)        |
| RAM              | 32 GB DDR4                                             |
| Operating System | Windows 11                                             |

The choice of hardware reflects a deliberate trade-off between experimental scope and practical feasibility. The RTX 4070 represents a mid-to-high-end consumer GPU with

sufficient compute capability to execute GPU-accelerated training for XGBoost and MLP models in reasonable time, while remaining accessible to many practitioners. The Ryzen 7 5700X provides adequate CPU performance for baseline models (Logistic Regression, Random Forest) and CPU-based XGBoost training. Together, this configuration enables direct comparison of CPU- and GPU-accelerated training on the same platform, which is central to answering one of the research questions (*How does energy consumption differ between CPU-based and GPU-based training for equivalent tasks?*).

It is important to note that energy consumption and CO2 emissions measured in this study are specific to this hardware configuration and the local electricity grid, and may not directly generalize to other systems or geographic regions. However, the relative performance comparisons (e.g., the energy efficiency ranking of different algorithms) are more likely to generalize, as they reflect algorithmic properties rather than hardware specifics alone.

### 5.1.2 Software Environment

All experiments were implemented in Python 3.12.0. The main libraries used are described below.

Scikit-learn [18] served as the foundation of the evaluation pipeline. It provided the `LogisticRegression` and `RandomForestClassifier` implementations, as well as `KFold` and `cross_validate` for cross-validation, `StandardScaler` for feature normalization, `make_pipeline` for chaining preprocessing and model steps, and `f1_score` and `make_scorer` for evaluation metrics.

The XGBoost library [13] was used for the gradient boosting model, as it provides a highly optimized implementation that supports both CPU and GPU training.

For the MLP, PyTorch [19] was used as the deep learning backend. To integrate the PyTorch model into the scikit-learn evaluation pipeline, the Skorch library [20] was used, which wraps PyTorch models in a scikit-learn-compatible interface.

Hyperparameter tuning for all models except Logistic Regression was performed using Optuna, as described in Section 4.6.

Carbon emissions and energy consumption were tracked using CodeCarbon [21], which is described in detail in Section 5.6.

To ensure reproducibility, a fixed random seed of 42 was used for all data splits, cross-validation folds, and model initialization. A `requirements.txt` file is provided so that the exact library versions used in this study can be reproduced.

## 5.2 Dataset Integration

The three datasets used in this study — *Wine*, *Credit*, and *HIGGS* — were introduced in Section 4.2. This section describes how they are integrated into the software architecture, covering the central configuration file, the data loading pipeline, and dataset-specific constraints.

### 5.2.1 Configuration Architecture

To ensure a consistent foundation across all model scripts, a central configuration file (`config.py`) was created. It serves as a single source of truth for all dataset-related settings, so that each script accesses the same parameters without redundant definitions.

For each dataset, the configuration stores the file path, the name of the target column, and an optional row limit (`nrows`). The row limit was particularly relevant for the *HIGGS* dataset, which contains 11 million instances, allowing experiments to be run on smaller subsets where needed. Beyond these common fields, the configuration also captures dataset-specific properties. For example, the *Credit* dataset includes a header row that must be skipped during loading, and the *Wine* dataset does not contain column names in the source file, which are therefore defined in the configuration directly. Additionally, a label offset is applied to the *Wine* target column, as its class labels are encoded as 1, 2, and 3 rather than starting at 0, which is required by the classifiers used in this study.

The global constants `RANDOM_STATE` and `CV_FOLDS` are also defined here, ensuring that all scripts use identical values for random seeding and cross-validation, which is essential for the comparability of results.

### 5.2.2 Data Loading Pipeline

To read the datasets from their respective files, a custom `load_data` method was implemented. Depending on the dataset, the appropriate loading mechanism is selected. The *Wine* and *Credit* datasets are loaded using pandas’ `read_csv` function. For the *Higgs* dataset, `read_parquet` is utilized. This was a deliberate decision to save storage space by storing the large *Higgs* dataset as a Parquet file rather than a standard CSV.

Following the initial loading phase, the *Higgs* data is reduced to a representative subset using a sampling approach controlled by the `nrows` parameter. Once the data size is managed, any columns specified in the configuration file are dropped from the respective dataset. The data is then split into the feature matrix  $X$  and the target vector  $y$ . If an offset is defined in the config, which is currently only the case for the *Credit* dataset, it is applied as described in the previous section. Finally, the method returns  $X$  and  $y$  for further use in the subsequent scripts. This process is visualized in Figure 5.1.

Due to the substantial scale of the *Higgs* dataset, several constraints were implemented to ensure the stability of the execution environment. Training a **Random Forest** model

on this specific data led to unmanageable processing times. For this reason, the **Random Forest** algorithm is explicitly bypassed for the *Higgs* dataset and the program terminates using `sys.exit(0)` to prevent system crashes. This allows the process to stay within the boundaries of the available hardware resources.

Figure 5.1: Visualization of the data loading pipeline and preprocessing steps within the `load_data()` method.

### 5.3 Reproducibility and Evaluation Design

To ensure fully reproducible results across all experiments, a global constant `RANDOM_STATE` with a value of 42 is utilized in every model script. This constant is applied to all functions requiring stochastic consistency. It is specifically passed to the `KFold` splitter, the `train_test_split` method, and the initialization of the machine learning models. For the multilayer perceptron, the random seed is explicitly set using `torch.manual_seed(RANDOM_STATE)` to guarantee deterministic weight initialization and training behavior.

The evaluation process relies on a standardized cross validation setup implemented uniformly across all scripts. The data is partitioned using `KFold` configured with five splits,

enabled shuffling, and the aforementioned random state. The execution is handled by the `cross_validate` function.

The performance metrics are evaluated using a custom scoring dictionary. This dictionary tracks both the standard accuracy and a weighted F1 score constructed via `make_scorer(f1_score, average="weighted")`. Once the evaluation is complete, the overall performance is aggregated by calculating the mean of the individual fold results, which is accessed through `cv_results["test_accuracy"].mean()` alongside the corresponding F1 score array. Having defined the measures of reproducibility and testing, the focus now shifts to the actual implementation of the predictive models.

## 5.4 Model Implementations

As outlined in Section 4.3, the following classification algorithms were employed to address the research questions mentioned previously. This section therefore details the specific implementation of each model.

### 5.4.1 Logistic Regression

The first baseline model is a standard logistic regression. To ensure that the model processes all features on an equal scale, the algorithm is embedded within a pipeline that starts with a `StandardScaler`. This initial scaling step is crucial for the stability and overall performance of the subsequent classification.

The regression itself is configured to use the Stochastic Average Gradient (SAG) algorithm by setting the `solver` parameter to `sag`. This specific solver is highly optimized for large datasets. It significantly reduces the memory footprint and the required training time, which is particularly important when evaluating the extensive *Higgs* data. To allow the solver enough room to converge properly, the maximum number of iterations is capped at 1000 via the `max_iter` parameter.

Deliberately, this model setup does not include any hyperparameter optimization. It serves as a fixed and reproducible baseline to accurately measure the pure computational times without the overhead of complex search algorithms.

### 5.4.2 Random Forest

The second baseline algorithm is the Random Forest classifier. This method belongs to the family of ensemble learning techniques. Unlike the logistic regression approach, this algorithm operates entirely without the need for prior feature scaling. To maximize computational efficiency, the execution is fully parallelized across all available CPU cores by setting the `n_jobs` parameter to `-1`. This deliberate configuration allows the processor to utilize its maximum capacity, which directly influences the subsequent energy consumption tracking and the overall runtime measurements.

An important methodological decision is the explicit exclusion of the *Higgs* dataset for this specific classifier. As already established in Section 5.2.2, training a Random Forest on such a massive volume of data leads to absurd runtimes. The primary research question focuses on the balance between energy consumption and predictive performance across varying dataset sizes and model complexities. Forcing this specific algorithm to process the *Higgs* data would result in an exponentially massive energy footprint and an excessive runtime. This extreme resource consumption would severely skew the comparative baseline without providing any proportional insights into the underlying scaling behavior. Therefore, the execution is bypassed to maintain a sensible and equitable evaluation framework.

To ensure maximum predictive capabilities for the remaining data, the model configurations were optimized using Optuna. The optimization process specifically targeted the maximization of the weighted F1 score. For the purpose of strict reproducibility, the finalized parameter combinations for both the *Wine* and the *Credit* dataset are documented in Table 5.2.

Table 5.2: Optimized hyperparameters for the Random Forest classifier obtained via Optuna optimization.

| Parameter         | <i>Wine</i> | <i>Credit</i> |
|-------------------|-------------|---------------|
| n_estimators      | 221         | 381           |
| max_depth         | 5           | 9             |
| min_samples_split | 8           | 10            |
| min_samples_leaf  | 3           | 2             |
| max_features      | sqrt        | None          |

### 5.4.3 XGBoost

The next algorithm from the family of tree ensemble models is the XGBoost classifier. This model serves as a direct point of comparison to the Random Forest. A primary reason for including XGBoost in this study is the ability to directly measure and contrast the computational efficiency between CPU and GPU. To achieve this the configuration dictionaries are kept identical across executions with the sole exception of the hardware device parameter being set to utilize the GPU. This controlled environment allows for a precise evaluation of the energy usage and emissions generated by the exact same model architecture on different hardware. This setup directly facilitates the investigation of the third research question *How does energy consumption differ between CPU-based and GPU-based training for equivalent tasks?*

Furthermore a specific technical requirement of the XGBoost framework must be addressed regarding the target variables. While the Random Forest algorithm natively adapts to different class structures XGBoost requires explicit instructions for its learning objective. As mentioned in Section 4.2 the *Wine* dataset consists of three distinct

categories. Therefore the objective parameter is set to `multi:softmax` paired with the `mlogloss` evaluation metric and a defined number of classes. In contrast the *Credit* and *Higgs* datasets contain only two categories. Consequently their objective is configured as `binary:logistic` evaluated via the standard `logloss` metric.

Similar to the previous baseline algorithm the parameters tailored to each dataset were determined using the Optuna optimization framework. Furthermore the algorithm processes the unscaled feature matrix  $X$  directly and uses the globally defined random state parameter to guarantee deterministic execution across all hardware setups. The resulting configurations utilized for the final training phase are detailed in Table 5.3.

Table 5.3: Optimized hyperparameters for the XGBoost classifier across all datasets.

| Parameter        | <i>Wine</i>                | <i>Credit</i>                | <i>Higgs</i>                 |
|------------------|----------------------------|------------------------------|------------------------------|
| objective        | <code>multi:softmax</code> | <code>binary:logistic</code> | <code>binary:logistic</code> |
| eval_metric      | <code>mlogloss</code>      | <code>logloss</code>         | <code>logloss</code>         |
| num_class        | 3                          | N/A                          | N/A                          |
| n_estimators     | 464                        | 108                          | 475                          |
| max_depth        | 7                          | 3                            | 8                            |
| learning_rate    | 0.0139                     | 0.2878                       | 0.2428                       |
| subsample        | 0.7790                     | 0.9640                       | 0.7100                       |
| colsample_bytree | 0.7500                     | 0.8430                       | 0.9368                       |
| min_child_weight | 5                          | 7                            | 2                            |

#### 5.4.4 Multilayer Perceptron

`MLPModule(nn.Module)`: dynamische Architektur aus `layer_sizes`-Liste. Jede Hidden Layer: `Linear`  $\rightarrow$  `BatchNorm1d`  $\rightarrow$  `ReLU`  $\rightarrow$  `Dropout`. Skorch `NeuralNetClassifier` als `sklearn`-Wrapper (`module__*`-Parameter-Konvention). CUDA-Detection: `torch.cuda.is_available()`. Datentypen: `X` als `float32`, `y` als `int64`. Adam-Optimizer, `CrossEntropyLoss`, `max_epochs=200`. Early Stopping via `skorch.callbacks.EarlyStopping` (dataset-spezifische `Patience`). Pipeline: `StandardScaler`  $\rightarrow$  `NeuralNetClassifier`.

## 5.5 Hyperparameter Optimization

### 5.5.1 Optuna as Tuning Framework

Nur Implementation, keine Begründung (die steht in Section 4.6):  
`optuna.create_study(direction="maximize")`.  
`TPESampler(seed=RANDOM_STATE)` für MLP (reproduzierbare Trial-Reihenfolge).  
`study.optimize(objective, n_trials=50)`. Tuning-Ergebnisse werden direkt als Hyperparameter-Dicts in die jeweiligen Model-Scripts übernommen.

### 5.5.2 Search Spaces per Model

Suchräume für XGB (`n_estimators`, `max_depth`, `learning_rate`, `subsample`, `colsample_bytree`, `min_child_weight`), RF (`n_estimators`, `max_depth`, `min_samples_split`, `min_samples_leaf`, `max_features`), MLP (`n_layers`, `layer_sizes`, `dropout_rate`, `lr`, `batch_size`). Tabelle oder kompakte Auflistung.

### 5.5.3 Tuning Strategy for HIGGS

MLP-Tuning auf HIGGS: stratifiziertes Subset via `-tune-sample-size` statt vollem Dataset. Train-Test-Split (80/20) statt CV für Tuning (Begründung: Laufzeit). Ergebnisse in `best_params_mlp_higgs.json`.

## 5.6 Emissions Measurement

Energy consumption and CO<sub>2</sub> emissions were tracked using *CodeCarbon* as described in Section 2.2. For the hardware configuration used in this study, GPU power was measured directly via hardware counters, while RAM was estimated at 10W. CPU power could not be measured directly on Windows and was therefore estimated at 32.5W based on 50% of the AMD Ryzen 7 5700X TDP, as discussed in Section 2.2. Figure 5.2 shows a visual representation of the process, from pre-processing to saving the results. Prior to training, data is loaded from the respective dataset and, where required, features are normalized using **StandardScaler**. Specifically, scaling was applied to Logistic Regression and MLP, as these models are sensitive to the magnitude of input features. Tree-based models (Random Forest, XGBoost) do not require feature scaling and were trained on the raw input data.

Each training run was wrapped in an **EmissionsTracker** instance, which monitored energy consumption across the full 5-fold cross-validation procedure. Upon completion, the tracker was stopped and the resulting emissions value, alongside accuracy, weighted F1-score, training time, and dataset size, was saved to a central `results.csv` file via the `save_results()` utility function. In addition, *CodeCarbon* writes its own emissions log to the `emissions/` directory, providing a detailed record of all tracked runs. The same tracking approach was applied during hyperparameter tuning, ensuring that the energy cost of the tuning process is also accounted for in the overall energy budget of this study.

Figure 5.2: Training and emissions tracking procedure per model-dataset combination. Dashed boxes indicate CodeCarbon `EmissionsTracker` calls.

Ggf. noch Subsections ergänzen: 5.6.1 CodeCarbon Integration, 5.6.2 Measurement Granularity (pro Modell  $\times$  Dataset, eindeutige `project_names`), 5.6.3 Limitations (CPU-Schätzung auf Windows, Background-Prozesse)

## 5.7 Inference Latency Measurement

Inference time was measured separately after training, outside the emissions tracker. For each model, a single sample from the test set was passed through the trained model and the elapsed time was recorded using `time.perf_counter()`. This provides a hardware-level estimate of per-sample prediction latency, which is relevant in deployment scenarios where repeated inference can accumulate significant energy costs [14].

Ergänzen: Begründung Single-Row statt Batch (Isolation von Training vs. Inference, kein Batch-Effekt). Modell kommt aus erstem CV-Fold (`cv_results["estimator"][0]`).

## 5.8 Results Persistence and Orchestration

### 5.8.1 Results Schema

results.csv Schema beschreiben: timestamp, model, dataset, nruns, accuracy, f1, co2eq\_kg, training\_time\_s. Append-Logik (kein Überschreiben) — Hinweis auf mögliche Duplikate bei Mehrfachläufen. inference\_time.csv analog. csv.DictWriter, Header-Check.

### 5.8.2 Experimental Orchestration

run\_models.py: subprocess.run() pro Dataset  $\times$  Modell-Kombination. Prozess-Isolation wichtig für CodeCarbon (prozessbasierte Messung). Fehlertoleranz: einzelne fehlgeschlagene Scripts blockieren nicht den Gesamtlauf.
